SI 618 - Homework 4: Map-Reduce in Python Using MrJob

Objectives:

- Get experience with the Map-Reduce computing paradigm.
- Practice how to break down a computing problem into Map-Reduce steps.
- Gain further experience implementing slightly more complex Map-Reduce code in Python using the MRJob module, using local data.
- You will be using input.txt for input in this assignment

Submission Instructions:

After completing this homework, you will turn in a zip file named si618 hw4 youruniquename.zip that contains four files via Canvas -> Assignments.

- 1. Your Python script, named si618 hw4_part1_YOUR_UNIQUE_NAME.py
- 2. Your output file, named si618 _hw4_output_part1_*YOUR_UNIQUE_NAME*.txt. This should be the output produced by your Python script.
- 3. Your Python script, named si618 _hw4_part2_*YOUR_UNIQUE_NAME*.py
- 4. Your output file, named si618 _hw4_output_part2_*YOUR_UNIQUE_NAME*.txt. This should be the output produced by your Python script.

This homework involves multiple steps. You should review all steps before starting, to think about how you're going to structure your code that can be used for both the earlier and later steps. You should then complete the steps one by one and verify that you've completed each correctly before moving on to the next one.

MRJob Documentation: https://pythonhosted.org/mrjob/

A quick intro to Object Oriented Programming:

https://jeffknupp.com/blog/2014/06/18/improve-your-python-python-classes-and-object-oriented-programming/

Step 1: Create a new Python file

This time, we will not be providing a template. Instead we will start with a blank file and build the program step by step. Create a new Python file and save it as si618_ hw4_part1_*YOUR_UNIQUE_NAME*.py

Step 2: Create an MRJob subclass

To create subclass (derived class) of MRJob, we first need to import the MRJob class into our file and then create our new class that inherits from MRJob. We can do this using:

from mrjob.job import MRJob

```
class MRMostUsedWord(MRJob):
   pass

if __name__ == "__main__":
   MRMostUsedWord.run()
```

We also need to call the 'run' method of the MRJob subclass MRMostUsedWord.

```
Step 3: Try running this file python si618_hw4_part1_YOUR_UNIQUE_NAME.py input.txt -o ./output
```

You will see an error like:

ValueError: Step has no mappers and no reducers

This error means that MrJob was imported and called successfully, but it is expecting you to define at least one mapper or reducer so that something is actually computed for the input file.

Step 4: Write a mapper that splits a line of input into words

Similar to what we did in the lab, we define a **mapper** function that takes a line from the input file as an input, splits it into words and yields a tuple in the form (WORD, COUNT_FOR_THIS_WORD). Remember, a mapper or reducer always return one or more (key, value) tuples.

```
class MRMostUsedWord(MRJob):
    def mapper(self, _, line):
        # your code goes here
```

We use _ as the second parameter as a convention, because we want to ignore any value that is passed as that parameter.

Use a regular expression to find **all long words (words with 4 letters)** in the line. Make sure you convert them to lowercase.

The mapper should produce, using the yield keyword, one tuple in the form (WORD, COUNT_FOR_THIS_WORD) for each word in the input line.

Congratulations, you just wrote the Mapping stage of the MapReduce flow.

Step 5: Write a combiner that sums up the count for each word

The shuffling stage re-distributes the mapping values by keyword so that they can be passed to the reducer to get a result. We want to minimize the network data transfer among nodes at the shuffling stage. So, we introduce the **combiner**. The combiner can consist of any operations that can minimize the data transfer at the shuffling stage. In our case, we can combine the counts of

keywords at each node, so that we don't send the same keyword, multiple times across the network.

The combiner function is similar to a mapper and a reducer, such that it also yields one or more (key, value) pairs.

In this combiner step, we sum up the counts of all different words at each node. Now your code should look something like this:

```
class MRMostUsedWord(MRJob):
    def mapper(self, _, line):
        # your code goes here

def combiner(self, word, counts):
    # your code goes here
```

The combiner method should produce, using the yield keyword, a tuple of the form (WORD, TOTAL_COUNT_FOR_WORD).

Step 6: Write a reducer that sums up the count for each word at the end

At this stage, the whole file has been read and we can now find out the final total count for each word. Your code should look something like this:

```
class MRMostUsedWord(MRJob):
    def mapper(self, _, line):
        # your code goes here

def combiner(self, word, counts):
        # your code goes here

def reducer(self, word, counts):
        # your code goes here
```

In this case, the arguments and the output of both combiner and reducer methods look the same, because they are essentially trying to do the same thing, but the combiner method is executed at an earlier stage than the reducer and both are usually executed at different computing nodes. Also, the reducer gets the final list of counts for each word and not an intermediate list like the combiner does.

```
Run your code:
```

```
Python3 si618_hw4_part1_YOUR_UNIQUE_NAME.py input.txt -o ./output
```

The output files /part-* under the output folder will contain the word frequency pairs.

Consolidate them under si618_hw4_output_part1_YOUR_UNIQUE_NAME.txt as follows:
cat ./output/part* > si618 hw4 output part1 YOUR_UNIQUE_NAME.txt

Your output should look like si618 hw4 part1 desired output.txt (on Canvas).

Step 7: Find out the most frequent word:

Now copy si618 hw4 part1 YOUR_UNIQUE_NAME.py to

si618_hw4_part2_**YOUR_UNIQUE_NAME**.py. You need to change your code now to identify the most frequent 4 letter word. The output of the reducer needs to be passed to the next step in the pipeline, which will find out the most frequently used word. This cannot be an independent step that is done in parallel, since selecting the maximum count is a comparison operation that requires counts for <u>all</u> words to be finished. So, the reducer should yield only values to be passed to the next step, i.e. it should yield a tuple in the form (None, TUPLE_OF_WORD_AND_TOTAL_COUNT). This will combine all the (WORD, TOTAL_COUNT_FOR_WORD) tuples as a list of tuples (technically a generator/lazy list of tuples) under the same key None, thus making it available to a single node for processing the most

```
As an example, typically we would yield (WORD, TOTAL_COUNT_FOR_WORD) or (TOTAL_COUNT_FOR_WORD, WORD), which would have resulted in an output like: ("apple", 1) ("mango", 2) ("banana", 3)
```

The above output yields multiple key, value tuples. In contrast to this, we want to pass such a tuple as a VALUE to the next step for processing, such that the key is None and the values get accumulated, i.e, we yield:

```
(None, ("apple", 1))
(None, ("mango", 2))
(None, ("banana", 3))
```

Step 8: Making our own MRSteps

frequent word in the next step.

So far, we have a mapper, combiner and reducer. A mapper pre-processes the data for further processing by a reducer. A combiner aggregates the data to limit the amount of copying between the different nodes. A reducer processes this data resulting in one or more key-value pairs (which is a tuple, not to be confused with a dictionary).

For the last step, finding the most frequent word across all word counts, we need a final reducer that takes the data from the previous reducer step and outputs the most frequent word. (A mapper isn't required because there is no pre-processing.) But, using the default configuration of MRJob, we cannot have a second method also named 'reducer'. To overcome this limitation, MRJob allows us to define additional custom computation steps using the MRStep class that allows us to write our own sequence of steps (defined using multiple MRStep objects) that MRJob should follow.

Here's an example of how to define two MRStep objects that perform the initial map/combine/reduce in the first MRStep, and the final reduce operation in the second MRStep. Your code should look like this:

```
from mrjob.job import MRJob
from mrjob.step import MRStep
import re
class MRMostUsedWord(MRJob):
 def mapper get words(self, , line):
   # your code goes here
 def combiner_count_words(self, word, counts):
   # your code goes here
 def reducer count words(self, word, counts):
   # your code goes here
 def reducer find max word(self, , word count pairs):
   # your code goes here
 def steps(self):
   return [
     MRStep(mapper=...,
         combiner=...,
         reducer=...),
     MRStep(reducer=...)
   1
```

Fill in the "...". Using the step method of MRJob, we can return a list of MRStep objects and thus control the flow of execution. The first MRStep uses a mapper, combiner and reducer, while the second MRStep uses a reducer that uses the data passed by the previous reducer to find the most frequent word.

Step 9: Find the most frequent word

Write the code for reducer_find_max_word such that it yields a tuple (WORD, TOTAL_COUNT) or (TOTAL_COUNT, WORD) for the most frequent word out of all words. The output may vary depending on whether you decide to use sort or max.

max function uses the first value in the tuple for comparison, whereas you can sort it and return the one tuple that represents the most frequent word.

Run this code:

The output file **part-00000** will contain only a single line consisting of either:

"WORD" TOTAL_COUNT

or

TOTAL_COUNT "WORD"

The desired output is therefore either:

"that" 47

or

47 "that"

Step 9: Rename output file

Rename the output file **part-00000** produced under the output folder as si618_hw4_output_part2_**YOUR_UNIQUE_NAME**.txt for submission.

Rubric:

Step 4 (writing the correct mapper): 20 pt

Step 5 (writing the correct combiner): 20 pt

Step 6 (writing the correct reducer for part-1): 20 pt

Step 7 (writing the correct reducer for the second step in part-2): 20pt

Step 8 (writing the correct step function): 20 pt
